Abstract. Nuclear speckles (speckles) represent a distinct nuclear compartment within the interchromatin space and are enriched in splicing factors. In a previous study (Melčák et al., 2001), it has been shown that the prespliceosomal assembly on microinjected splicing-competent precursor mRNA takes place in the speckles, and it has been suggested that the targeting of RNA into speckles consists of two interdependent steps, namely the diffusion process, followed by the energy-dependent translocation of RNA into the speckles. In the present study, we confirm the existence of these two steps and show that this latter translocation is ATP dependent.

Most primary transcripts of mammalian protein-coding genes contain introns and have to be spliced before being transported to the cytoplasm. Precursor mRNA (pre-mRNA) splicing takes place in a large ribonucleoprotein complex termed spliceosome. The spliceosomes are generated by the constitutive assembly of U1, U2, U5, U4/U6 small nuclear ribonucleoprotein particles (snRNPs) and various non-snRNP factors on pre-mRNAs in a cascade of sequence-specific steps (Steitz et al., 1988; Lamm and Lamond, 1993; Moore et al., 1993; Newman, 1994; Krämer, 1996). The formation of the functional spliceosome is thus preceded by the formation of a number of pre-spliceosomal complexes which contain, together with unspliced pre-mRNA, defined combinations of snRNP particles and non-snRNP factors (e.g. Steitz et al., 1988; Lamm and Lamond, 1993; Moore et al., 1993; Newman, 1994; Krämer, 1996).

When RNA polymerase II transcriptional and splicing components are mapped within the cell nucleus, they exhibit frequent sites of high local accumulation in the form of microclusters, which likely represent the sites of active transcription and co-transcriptional splicing (Neugebauer and Roth, 1997; Misteli and Spector, 1998). On the other hand, beside these microclusters, an accumulation of factors of the splicing apparatus is typically mapped to spatially distinct and large domains termed „speckles“, „SC35 domains“, the antibody to splicing factor SC35 (Fu and Maniatis, 1990) being used regularly for the visualization of speckles, or „splicing factor compartments“ (reviewed in Spector, 1990; Fakan, 1994; Misteli, 2000). Even though there is a consensus that speckles play a role in RNA metabolism, their exact function is presently unknown. These structures are not usually correlated with RNA polymerase II transcription, but it has been shown at the level of activation of some specific unique genes that speckles serve as pools of splicing factors, which are redistributed to the transcription/splicing sites (Misteli et al., 1997).

The splicing of pre-mRNAs may be a co-transcriptional event (Beyer and Osheim, 1988; Neugebauer and Roth, 1997; Custodio et al., 1999), and it has been shown that transcription and splicing are coupled through interactions of certain factors participating in both these processes (Corden and Patturajan, 1997; McCracken et al., 1997; Steinmetz,

Abbreviations: pre-mRNA – precursor messenger RNA, snRNP – small nuclear ribonucleoprotein.

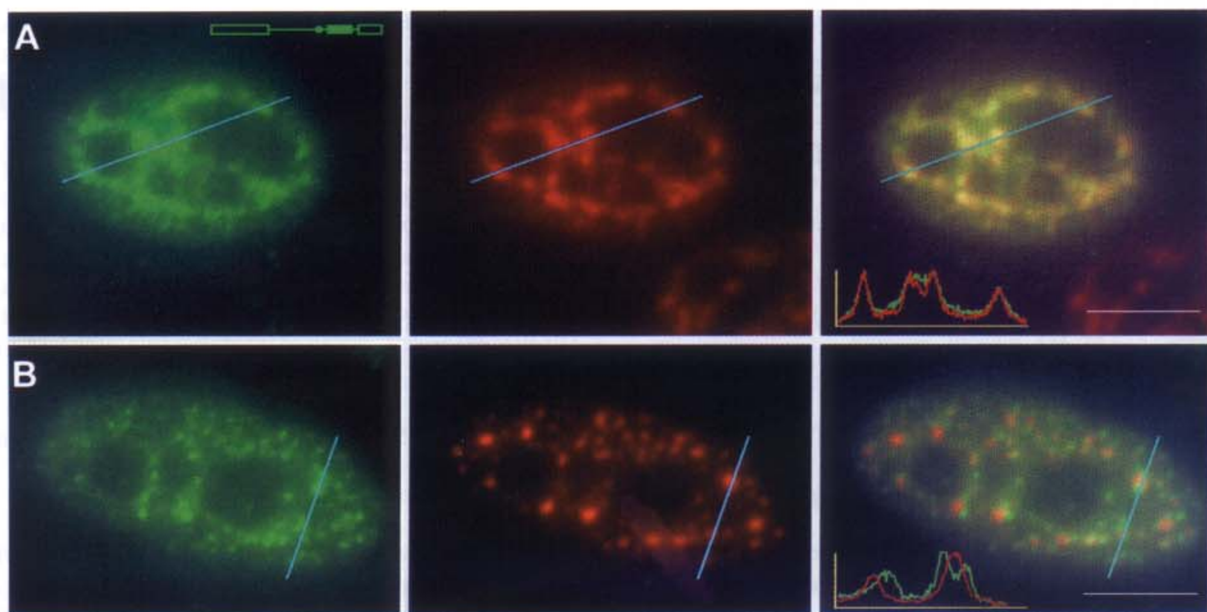

Fig. 1. (A, B) After the consecutive microinjection of apyrase (B) or buffer (A), and of the Ad1 RNA labelled with fluorochrome (in green), the cells were incubated at 37°C for 15 min. The cells were then labelled for the SC35 splicing factor (in red). The form of the Ad1 RNA, consisting of two exons and one intron, is shown in A. Note a part of a non-microinjected nucleus in A. The two left columns correspond to individual colour channels, the right column is the overlay. In A, RNA was accumulated within the speckles. In B, the ATP depletion resulted in the accumulation of RNA in dots adjacent to the speckles. In the quantitative evaluation (inserts in A and B), fluorescence intensities along the blue lines shown in A and B were scaled to the minimum and maximum values. The identical position of peaks A (insert) in the two colour channels testifies to the accumulation of RNAs in the speckles. Note the differences in the position of peaks in B (insert). The bar in A and B corresponds to 4 µm.

1997). However, not all pre-mRNA sequences are processed co-transcriptionally and post-transcriptional splicing does occur (Zachar et al., 1993; Baurén and Wieslander, 1994; Wuarin and Schibler, 1994). Importantly, isolated pre-mRNAs from mammalian cells may contain both introns and poly(A) tails. Splicing may then be a post-transcriptional event, at least in some cases (McCracken et al., 1997; Minvielle-Sebastia and Keller, 1999), and it has been suggested that speckles are involved in post-transcriptional splicing (Melčák and Raška, 1996). With regard to the spatial relationship of pre-mRNA accumulations relative to speckle domains of splicing factor accumulations, primary transcripts of certain genes as well as the spliced RNAs have been mapped at sites of active transcription and/or outside the speckles (Zhang et al., 1994; Smith et al., 1999). However, pre-mRNAs from some other genes have been shown to be associated, or overlapped, with nuclear speckles (Xing et al., 1993, 1995; Huang and Spector, 1996; Dirks et al., 1997; Ishov et al., 1997; Jolly et al., 1999; Smith et al., 1999; Snaar et al., 1999; Johnson et al, 2000; Melčák et al., 2000).

The suggested function of speckles in splicing has been probed using a completely different approach in which the behavior of microinjected (and fluorochrome-labelled) pre-mRNA into the nuclei of Hela cells was investigated (Wang et al., 1991; Melčák et al., 2001). The rationale for this approach is based on the findings of Graessmann and Graessmann (1982) that microinjected intron-containing RNA is processed into functional mRNA within the cell nucleus. These exogenous RNAs skip the transcription context and behave similarly to endogenous unspliced RNAs released from the sites of transcription. Using model RNAs with a single intron, it has been shown that these RNAs rapidly accumulate in the speckles after microinjection in a process that is dependent on the intron (Wang et al., 1991; Melčák et al., 2001) and that the pre-spliceosome assembly on RNAs takes place within the speckles (Wang et al., 1991; Melčák et al., 2001). RNA targeting to and accumulation within the speckles is the result of the cumulative loading of splicing factors to the pre-mRNA.

In this study, we expand the results with microinjected adenovirus pre-mRNAs and demonstrate that the targeting of microinjected pre-mRNA, together with formed pre-spliceosomal complexes, to the speckles consists of two interdependent steps, namely the movement of pre-mRNA towards the speckles and its translocation into the speckles, this second step requiring ATP.

Material and Methods

Synthesis of the fluorochrome-labelled and splicing-competent adenovirus Ad1 RNA, containing a single

intron, as well as HeLa cell culture, microinjection, SC35 immunolabelling and microscopy were performed according to Melčák et al. (2001).

In order to determine the effect of energy depletion on RNA localization, an ATP depletion by microinjected apyrase was performed. In order to reach this aim, consecutive microinjections were performed. Cells were microinjected with 500 U/ml of apyrase in 5 mM Tris-acetate, pH 6.95, and incubated for 5 min at 37°C. The same cells were then microinjected with RNA, washed with fresh prewarmed medium and incubated for 15 min at 37°C. The control cells were, instead of apyrase, microinjected with buffer only.

Four series of experiments were perfomed and 30 to 40 cells were microinjected in each experiment. However, not all microinjected cells could be subsequently investigated because a few cells either detached from the support or were disrupted. Also for this reason the described fluorescence pattern after apyrase microinjection (Fig. 1) was observed in 75, 85, 89 and 90% of microinjected cells.

Results and Discussion

The control experiment was found to be compatible with the findings in previous studies (Wang et al., 1991; Melčák et al., 2001) and documented the rapid movement of microinjected splicing-competent Ad1 pre-mRNA into the speckles. The RNA was localized within the speckles, which were depicted by SC35 labelling (Fig. 1A).

A striking change in the RNA distribution was seen when the RNA microinjection was preceded by apyrase microinjection. RNA was also targeted towards the speckles, but remained accumulated outside this nuclear compartment. It formed dots of accumulated RNA adjacent to the speckles (Fig. 1B). Moreover, the speckles rounded up. As the ATP depletion necessarily led to transcription inhibition, the rounding up of the speckles was in agreement with previous results (e.g. O'Keefe et al., 1994; Melčák et al., 2000) documenting that the normal pattern of speckles is converted into round speckles in transcriptionally inactive cells.

The fluorescence pattern testified to the existence of an ATP-dependent step, which allowed for RNA accumulation within the speckles. Importantly, the fluorescence pattern was compatible with the experiment in which microinjected HeLa cells with Ad1 RNA were kept at 4°C, and strikingly resembled the fluorescence pattern observed with several microinjected mutant RNAs (Melčák et al., 2001). The mutant RNAs allow for the generation of pre-spliceosomal complexes, but only of such complexes which do not require ATP for their formation in *in vitro* experiments (Seraphin and Rosbach, 1989; Bennett et al., 1992, Michaud and Reed, 1993; Query et al., 1997; see Melčák et al. (2001) for detailed discussion).

In our previous study (Melčák et al., 2001), it was suggested that the targeting of microinjected splicing-competent RNA into speckles consisted of two interdependent steps, namely the movement of RNA towards the speckles, probably as a diffusion process, followed by the energy-dependent translocation of RNA into the speckles. The result of the performed ATP depletion experiment, which resulted, on the one hand, in the blocking of accumulation of the splicing-competent RNAs in the speckles, but, on the other, in their accumulation in the fluorescent dots adjacent to the speckles, demonstrates the existence of these two targeting steps, and supports the concept that nuclear speckles are involved in splicing.

Acknowledgement

The authors wish to thank Dr. X.-D. Fu (Univ. California San Diego) for the anti-SC35 antibody, and Dr. C. Will (Univ. of Marburg) for the plasmid used for the preparation of RNA. They thank Dr. J. Malínský for help with the preparation of Figure and Dr. F. Raška for the English revision.
